## Abstract

I examine the mean consensus time (i.e., exit time) of the voter model in the so-called two-clique graph. The two-clique graph is composed of two cliques interconnected by some links and considered as a toy model of networks with community structure or multilayer networks. I analytically show that, as the number of interclique links per node is varied, the mean consensus time experiences a crossover between a fast consensus regime (i.e.,  $O(N)$ ) and a slow consensus regime (i.e.,  $O(N^2)$ ), where  $N$  is the number of nodes. The fast regime is consistent with the result for homogeneous well-mixed graphs such as the complete graph. The slow regime appears only when the entire network has  $O(1)$  interclique links. The present results suggest that the effect of community structure on the consensus time of the voter model is fairly limited.

## I. INTRODUCTION

In collective opinion formation taking place in a population of interacting agents, competing opinions are often approximately as strong as each other. The voter model is a simple stochastic process to represent competitive dynamics between equally strong states (i.e., opinions) [1–4]. In the voter model, an agent flips its state to a new state with a rate proportional to the number of neighboring agents that possess the new state.

Social networks in which opinion formation takes place are usually complex. In particular, community structure, in which connection is dense within groups and sparse across different groups, is a hallmark of a majority of social networks. A community would correspond to a circle of friends, school class, organisation, household, and so on [5]. Consensus formation in networks with community structure may need long time because communities are sparsely connected to each other by definition and different communities have to align their states for the consensus in the entire network to be reached. In fact, in the voter model in metapopulation networks in which agents randomly diffuse from one metapopulation to another, a small diffusion rate (corresponding to sparse connectivity between communities) slows down consensus [6]. In addition, consensus is often hampered in other opinion formation models when the network possesses community structure [7–12].

However, the extent to which the community structure slows down the consensus dynamics is unclear. Previous numerical results suggest that the dependence of the time to consensus on the number of nodes does not differ between networks with and without community structure [13]. The consensus time is also independent of the network structure for a related model of language exchange [14]. In the present study, I confine myself to a toy network model mimicking community structure and also multilayer networks [15], called the two-clique graph. The voter model in this graph was briefly analysed in Ref. [16]. For the two-clique graph, I reveal the scaling relationship between the time to consensus and the number of nodes, which depends on the number of links connecting two cliques.

## II. MODEL

Consider a graph in which each of the two cliques has  $N$  nodes [16]; the entire network has  $2N$  nodes. The two cliques are connected by  $M$  ( $0 < M \leq N^2$ ) interclique links. Each

node has

$$C \equiv M/N \quad (1)$$

interclique links on average. The interclique links are either regularly placed such that each node has (approximately)  $C$  interclique links or randomly placed such that the number of interclique links that a node possesses obeys a binomial distribution with mean  $C$ .

I run a variant of the two-state voter model according to the link dynamics rule [16–19] on this network. Specifically, each node takes either of the two states  $\mathbf{0}$  and  $\mathbf{1}$ . Initially,  $N/2$  voters in each clique are assumed to be in the  $\mathbf{0}$  state. The other  $N/2$  voters in each clique are in the  $\mathbf{1}$  state. In each time step, I randomly pick a link with the equal probability, i.e.,  $1/[N(N-1)+M]$ , and then select one of the two endpoints of the link with probability  $1/2$ . Then, the selected node copies the state of the other endpoint of the link. Then, I move forward the clock by time  $1/2N$  such that each node is updated once on average in unit time. The dynamics eventually reaches the consensus of either state. Denote the consensus time and its mean by  $T$  and  $\langle T \rangle$ , respectively.

### III. FOKKER-PLANCK EQUATION

The Fokker-Planck equation for this dynamics was previously formulated [16]. For the Fokker-Planck equation to be valid, it is necessary that each node has exactly  $C$  interclique links or  $C$  is large such that the fluctuation in the number of interclique links per node is negligible. The Fokker-Planck equation in terms of the density of  $\mathbf{1}$  voters in the two cliques, denoted by  $\rho_1$  and  $\rho_2$ , is given by

$$\begin{aligned} \frac{\partial P}{\partial t} = & -\frac{\partial}{\partial \rho_1} \left[ \frac{C}{N+C} (\rho_2 - \rho_1) P \right] - \frac{\partial}{\partial \rho_2} \left[ \frac{C}{N+C} (\rho_1 - \rho_2) P \right] \\ & + \frac{1}{2} \frac{\partial^2}{\partial^2 \rho_1^2} \left[ \left( \frac{\rho_1 (1 - \rho_1)}{N+C} + \frac{\frac{C}{2N} (\rho_1 + \rho_2 - 2\rho_1 \rho_2)}{N+C} \right) P \right] \\ & + \frac{1}{2} \frac{\partial^2}{\partial^2 \rho_2^2} \left[ \left( \frac{\rho_2 (1 - \rho_2)}{N+C} + \frac{\frac{C}{2N} (\rho_1 + \rho_2 - 2\rho_1 \rho_2)}{N+C} \right) P \right], \end{aligned} \quad (2)$$

where  $P = P(\rho_1, \rho_2, t)$  represents the probability density.

When  $C \gg 1$ , Eq. (2) implies that the drift term dominates over the diffusion term. This case was previously solved for more general network structure by adiabatic approximation [14, 20]. In the case of the two-clique graph, the density in both cliques relaxes to  $(\rho_1 + \rho_2)/2$

on a fast time scale. The dynamics on a slow time scale, which leads to the consensus in the entire population, is essentially the same as that for the complete graph. Therefore,  $\langle T \rangle \approx 2N \ln 2$  [16].

When  $C = O(1)$ , the drift and diffusion terms are comparable. In this case, the problem is essentially two-dimensional and seems difficult to solve.

When  $C \ll 1$ , the diffusion terms are dominant on a fast time scale. In this situation, the approximate consensus within each clique may be reached before the two cliques effectively start to interact. If this is the case, the bias terms play a role after the consensus in each clique has been reached. In fact, the Fokker-Planck approximation given by Eq. (2) breaks down when  $C \ll 1$  because the number of interclique links crucially differs node by node. In other words, most nodes possess either zero or one interclique link, and not having any interclique link and having one interclique link may result in substantially different behaviour of nodes.

#### IV. ASSESSING THE MEAN CONSENSUS TIME WHEN $C \ll 1$

In this section, I estimate  $\langle T \rangle$  in a hypothetical situation in which consensus in each clique is realised fast enough before an interclique link is selected to trigger interaction of the two cliques. If the two cliques are disconnected, the consensus in each clique is realised with mean time  $N \ln 2$ . The mean time before an interclique link is selected, denoted by  $\langle t_{ic} \rangle$ , is given by

$$\langle t_{ic} \rangle = \frac{1}{N} \left[ \frac{CN}{N(N-1) + CN} \right]^{-1} = O(1/C), \quad (3)$$

because there are  $CN$  interclique links and  $N(N-1)$  intraclique links, and selection of a link consumes time  $1/N$ . Therefore, the condition under which the following adiabatic approximation is valid is given by  $N \ln 2 \ll O(1/C)$ , i.e.,  $C \ll 1/N$ .

Because links are implicitly assumed to be unweighted,  $C \geq 1/N$ , where the equality is realised when there is just one interclique link in the entire network. Therefore, the condition  $C \ll 1/N$  is never satisfied. Nevertheless, the arguments in the remainder of this section turn out to predict the correct dependence of  $\langle T \rangle$  on  $C$  when  $C(\geq 1/N)$  is small, which is derived in section V B. If weighted links are allowed,  $C \ll 1/N$  can be realised if, for example, there are  $O(1)$  interclique links whose weights are much smaller than unity.

Under the assumption  $C \ll 1/N$ , the consensus is reached in cliques 1 and 2 on a fast

time scale. The consensus within each clique implies the consensus of the entire network with probability  $1/2$ . Otherwise, I assume without loss of generality that clique 1 reaches the **0** consensus and clique 2 reaches the **1** consensus. This event occurs with probability  $1/2$ . In the latter case, the consensus of the entire network is realised on a slow time scale.

If the two cliques have reached the consensus of the opposite states, without loss of generality, the event that happens next is invasion of the **0** state into a node in clique 2 via an interclique link. This event occurs when an interclique link is selected for an update, which takes mean time  $\langle t_{ic} \rangle$ .

Then, one of the following two scenarios ensues. In the first scenario, state **0** fixates in clique 2, and the consensus of the entire network is reached. This event occurs with probability  $1/N$  [21, 22]. Under the condition that state **0** fixates in clique 2, the mean fixation time in clique 2 is equal to (e.g., [16, 22])

$$N \frac{1 - \frac{1}{N}}{\frac{1}{N}} \ln \frac{1}{1 - \frac{1}{N}} = O(N). \quad (4)$$

Therefore, the consensus time is dominated by  $\langle t_{ic} \rangle = O(1/C)$ . Here I ignored the contribution of  $N \ln 2$  derived from the initial intraclique consensus and that given by Eq. (4) because  $C \ll 1/N$  is assumed.

In the second scenario, state **1** fixates in clique 2. This scenario occurs with probability  $(N - 1)/N$ . Under the condition that state **1** fixates in clique 2, the mean fixation time in clique 2 is equal to

$$N \frac{\frac{1}{N}}{1 - \frac{1}{N}} \ln \frac{1}{\frac{1}{N}} = O(\ln N). \quad (5)$$

In this case, the situation in which cliques 1 and 2 are in the consensus of the opposite states is revisited. Then, either state invades the other state in the opposite clique after mean time  $\langle t_{ic} \rangle$ , and the same process repeats until the consensus of the entire network is reached.

Therefore, I obtain

$$\begin{aligned} \langle T \rangle &\approx N \ln 2 + \frac{1}{2} \frac{1}{N} \langle t_{ic} \rangle + \frac{1}{2} \frac{N - 1}{N} \frac{1}{N} [\langle t_{ic} \rangle + O(\ln N) + \langle t_{ic} \rangle] \\ &\quad + \frac{1}{2} \left( \frac{N - 1}{N} \right)^2 \frac{1}{N} [\langle t_{ic} \rangle + O(\ln N) + \langle t_{ic} \rangle + O(\ln N) + \langle t_{ic} \rangle] + \dots \\ &= N \langle t_{ic} \rangle = O(N/C). \end{aligned} \quad (6)$$

Equation (6) implies that consensus is much slower as compared to the case of the complete graph (i.e.,  $\langle T \rangle = O(N)$ ). Extrapolation of Eq. (6) to the case of  $O(1)$  interclique links in

the networks, i.e.,  $C = O(1/N)$ , would lead to  $\langle T \rangle = O(N^2)$ , which is actually correct as theoretically and numerically shown in sections V and VI, respectively.

The reasoning above implies that the consensus occurs fast (i.e.,  $O(N)$  time) or slowly (i.e.,  $O(N/C)$  time) with probability  $1/2$  each. Consensus of the opposite states in the different cliques does not occur in the former case, and it occurs in the latter case. To validate this point, I carried out  $10^4$  runs of the voter model with  $N = 10^4$  and  $M = 1$ . Half the nodes in each clique was initially assumed to take the  $\mathbf{0}$  state. The numerically obtained histogram of  $T$  is shown in Fig. 1. The distribution of  $T$  is in fact bimodal with a heavy tail (note the logscale of the abscissa). Each peak contains roughly half the runs. In addition, the positions of the two peaks are roughly separated by  $1/C = 10^4$  times, which is consistent with the ratio between the  $O(N)$  and  $O(N/C)$  consensus time estimated for each peak.

## V. MEAN CONSENSUS TIME OBTAINED FROM THE COALESCING RANDOM WALK

To assess  $\langle T \rangle$  for the entire range of  $C$ , let us turn to a different and in fact more solid method on the basis of the random walk.

The dual process of the voter model is the coalescing random walk, in which walkers visiting the same node coalesce into a single walker. For arbitrary networks, the consensus time is equal to the time needed for the  $N$  simple random walkers, one walker initially located per node, to coalesce into one [1, 23–25]. The time needed for the last two walkers to coalesce is considered to dominate the consensus time. Therefore, in this section I estimate the mean consensus time by analysing the mean time before the two walkers starting from random positions meet.

### A. When each node has many interclique links

When  $C \gg 1$ , the number of interclique links for a node does not differ much among the nodes. Therefore, I coarse grain the network to regard that all the nodes in the same clique are structurally the same, as implicitly assumed in the derivation of the Fokker-Planck equation (Eq. (2)). The following analysis is also valid when each node has exactly

$C$  interclique links and  $C = O(1)$ .

Denote by  $p_1(t)$  the probability that the two walkers are located at different nodes in the same clique at time  $t$ . Denote by  $p_2(t)$  the probability that the two walkers are located in the opposite cliques at time  $t$ . Finally,  $r(t)$  is the probability that the two walkers coalesce at time  $t$ . In each time step, one of the two walkers is selected with probability  $1/2$  and moves to a neighbor according to the simple random walk. The selected walker moves to a neighbor with probability  $1/(N + C - 1) \equiv 1/\Delta$ . The network under consideration is regular. Therefore, the simple random walk is equivalent to selecting an arbitrary link and its direction with probability  $1/2M$  and moving a walker (if any) along the direction of the selected link, up to a time rescaling.

I obtain

$$\begin{pmatrix} p_1(t) \\ p_2(t) \end{pmatrix} = A^t \begin{pmatrix} p_1(0) \\ p_2(0) \end{pmatrix} \quad (7)$$

and

$$r(t+1) = v_1 p_1(t) + v_2 p_2(t), \quad (8)$$

where

$$A \equiv \frac{1}{\Delta} \begin{pmatrix} N-2 & \frac{(N-1)C}{N} \\ C & N-1 \end{pmatrix} \quad (9)$$

and

$$\mathbf{v} \equiv (v_1 \ v_2) = \frac{1}{\Delta} \begin{pmatrix} 1 & C \\ 1 & N \end{pmatrix}. \quad (10)$$

By using

$$(I - A)^{-1} = \frac{\Delta N}{(N + C)C} \begin{pmatrix} C & \frac{(N-1)C}{N} \\ C & C + 1 \end{pmatrix}, \quad (11)$$

one can verify

$$\begin{aligned} \sum_{t=1}^{\infty} r(t) &= \sum_{t=1}^{\infty} \mathbf{v} A^{t-1} \begin{pmatrix} p_1(0) \\ p_2(0) \end{pmatrix} \\ &= \mathbf{v} (I - A)^{-1} \begin{pmatrix} p_1(0) \\ p_2(0) \end{pmatrix} \\ &= p_1(0) + p_2(0) = 1 \end{aligned} \quad (12)$$

regardless of  $p_1(0)$  and  $p_2(0)$ . By ignoring the transient process in which the  $N$  random

walkers coalesce into two random walkers, the mean consensus time is evaluated as

$$\begin{aligned}
\langle T \rangle &\approx \sum_{t=1}^{\infty} tr(t) = \mathbf{v}(I - A)^{-2} \begin{pmatrix} p_1(0) \\ p_2(0) \end{pmatrix} \\
&= (1 \ 1)(I - A)^{-1} \begin{pmatrix} p_1(0) \\ p_2(0) \end{pmatrix} \\
&= \frac{(N + C - 1)N}{(N + C)C} \left[ 2Cp_1(0) + \left( 1 - \frac{C}{N} + 2C \right) p_2(0) \right]. \tag{13}
\end{aligned}$$

If  $C \gg 1$ , I obtain  $2Cp_1(0) \gg (1 - C/N)p_2(0)$  unless  $p_1(0) = 0$ , which leads to  $\langle T \rangle = O(N)$ . It should be noted that, even for  $C = O(1)$ , Eq. (13) implies  $\langle T \rangle = O(N)$ . Therefore, the transition between the  $\langle T \rangle = O(N^2)$  and  $\langle T \rangle = O(N)$  regimes occurs at a  $C \ll 1$  value when  $C$  is varied.

### B. When each node has at most one interclique link

Equation (13) extrapolated to the case  $C < 1$  indicates  $\langle T \rangle = O(N/C)$ . In particular, substitution of  $C = O(1/N)$  in Eq. (13) yields  $\langle T \rangle = O(N^2)$ , which is consistent with the estimation derived in section IV. However, the assumption that each node has  $C$  interclique links, which justified the annealed approximation developed in section V A, breaks down when  $C < 1$ . When  $C < 1$ , some nodes do not possess any interclique link, whereas other nodes typically possess one interclique link. A single-step random walk starting from a node without an interclique link and that with an interclique link may be substantially different because only the latter allows the transition to the opposite clique.

In this section, I carry out a quenched analysis of the coalescing random walk for the case  $C < 1$ . Assume that  $NC$  nodes in each clique has one interclique link each, and  $N(1 - C)$  nodes in each clique does not have any interclique link. I have implicitly assumed that different interclique links do not share an endpoint. These assumptions exactly hold true when  $C \ll 1$ . I consider two coalescing random walkers starting from different positions and assess the coalescing time, as was done in section V A.

The nodes in the two-clique graph are divided into four equivalent classes, as shown in Fig. 2. The first class of nodes, which is called class  $a$ , contains  $N(1 - C)$  nodes in clique 1 that are not an endpoint of any interclique link. The second class, which is called class  $b$ , contains  $NC$  nodes in clique 1 that are an endpoint of an interclique link. The third class, which is called class  $c$ , contains  $NC$  nodes in clique 2 that are an endpoint of an interclique

link. The fourth class, which is called class  $d$ , contains  $N(1 - C)$  nodes in clique 2 that are not an endpoint of any interclique link.

At any time  $t$ , the coalescing random walk takes either of the following six states, as shown in Fig. 3, unless the two walkers coalesce. Denote by  $(i, j)$  ( $i, j \in \{a, b, c, d\}$ ) the event that two random walkers are located at a class  $i$  node and a class  $j$  node. Denote by  $p_1(t)$  the probability that both walkers visit two different nodes in class 1 (i.e.,  $(a, a)$ ) or in class 4 (i.e.,  $(d, d)$ ) at time  $t$ . The sum of the probability of  $(a, b)$  and that of  $(c, d)$  is denoted by  $p_2(t)$ . The sum of the probability of  $(a, c)$  and that of  $(b, d)$  is denoted by  $p_3(t)$ . The probability of  $(a, d)$  is denoted by  $p_4(t)$ . The sum of the probability of  $(b, b)$  and that of  $(c, c)$  is denoted by  $p_5(t)$ . Finally, the probability of  $(b, c)$  is denoted by  $p_6(t)$ .

In each time step, one of the  $N(N + C - 1)$  links in the network is selected with the equal probability, i.e.,  $1/[N(N + C - 1)]$ . Then, one of the two endpoints of the link selected with probability  $1/2$  adopts the state of the other endpoint. To explain the calculation of  $A_{ij}$ , i.e., the transition probability from state  $j$  to state  $i$  ( $1 \leq i, j \leq 6$ ), consider state 1, in which the two walkers occupy different class- $a$  nodes (Fig. 3). There are three possible types of state transition in one time step. First, one of the two walkers moves to a node in class  $b$ . This event occurs with probability  $A_{21} = 2NC/[N(N + C - 1)] \times (1/2) = C/(N + C - 1)$ . Second, the two walkers coalesce with probability  $2/[N(N + C - 1)] \times (1/2) = 1/[N(N + C - 1)]$ . Otherwise, the state does not change such that  $A_{11} = 1 - C/(N + C - 1) - 1/[N(N + C - 1)]$ .

One can write down  $A = (A_{ij})$ , the six-dimensional vector  $\mathbf{v}$ , and the mean coalescing time as a linear sum of  $p_1(0), \dots, p_6(0)$  in the same manner as in section V A. The detailed calculations are shown in Appendix. In summary, the obtained scaling agrees with that estimated in Eq. (6), i.e.,

$$\langle T \rangle = O(N/C). \quad (14)$$

Substitution of  $C = O(1/N)$  in Eq. (14) yields  $\langle T \rangle = O(N^2)$ . This is the same scaling as the case of the one-dimensional lattice [2, 4, 25]. It should be noted that, even if  $C = O(1/N)$ , the network diameter is equal to just three, and the mean path length between a pair of nodes is small; it is approximately equal to  $(1/2) \times 1 + (1/2) \times 3 = 2$  independent of  $N$ .

## VI. NUMERICAL SIMULATIONS

I perform 1000 runs for a given set of parameter values  $(N, M)$  and calculate  $\langle T \rangle$ . A new two-clique graph is generated for each run. Same as the numerical simulations for Fig. 1, the initial condition is such that half the randomly selected nodes in each clique takes the **0** state and the other half the **1** state.

By factoring out  $1/(N + C)$  on the right-hand side of Eq. (2) and assuming  $C \ll N$ , I obtain the the following scaling ansatz:

$$\frac{\langle T \rangle}{N} = f\left(\frac{M}{N}\right), \quad (15)$$

where  $f$  is a scaling function. In Fig. 4,  $\langle T \rangle / N$  is plotted against  $M/N$  for  $N = 10^2, 10^3$ , and  $10^4$  and various  $M$  values. The results for different values of  $N$  and  $M$  nicely collapse on a single curve, confirming the validity of Eq. (15).

When  $C = M/N \gg 1$ , the network approaches the complete graph such that  $\langle T \rangle = 2N \ln 2$ . In fact,  $\langle T \rangle \approx 2N \ln 2$  holds true even if  $C = O(1)$ ; the horizontal dotted line in Fig. 4 indicates  $\langle T \rangle / N = 2 \ln 2$ . When  $C = O(1/N)$ , combination of Eqs. (14) and (15) yields  $f(x) \propto x^{-1}$  as  $x \rightarrow 0$ . Figure 4 indicates that this relationship holds true for small  $x$ ; the solid line represents  $\langle T \rangle / N \propto (M/N)^{-1}$ .

## VII. DISCUSSION

I examined the consensus time of a variant of the voter model on the two-clique graph. Theoretically, the mean consensus time  $\langle T \rangle = O(N)$  when there are many (i.e.,  $\gg 1$ ) interclique links per node. Numerically,  $O(1)$  interclique links per node is sufficient to realise the same scaling. When the number of interclique links per node is much smaller than unity,  $\langle T \rangle = O(N^2)$ . The crossover between the two regimes seems to occur at approximately one interclique link per node (Fig. 4). Therefore, the voter model dynamics is considerably decelerated only when the two cliques are very sparsely connected. It is straightforward to extend the present results to the case of more than two cliques.

The present results are consistent with the previous numerical results showing that networks with community structure in which intercommunity links are not rare yield  $\langle T \rangle = O(N)$  [13]. A social network with an extremely sparse connectivity between communities is unrealistic. It may bear some realism in the context of genetic evolutionary dynamics,

for which invasion dynamics between sparsely interacting populations was recently analyzed [26].

In general, the two-clique graph defined in the present study is not regular in the node degree. In nonregular networks, behaviour of the voter model depends on the rule according to which the node's state is updated. The so-called link dynamics rule [16, 19] was used in the present study. In general, the results remain the same under different updating rules (i.e., invasion process [16, 17, 19] and the so-called voter model rule [16, 18, 19, 27, 28]) if the network is regular. In the two-clique graph, the degree of each node is equal to  $N - 1$  plus the number of interclique links. When the interclique links are placed randomly, the number of interclique links obeys the binomial distribution. However, its mean (i.e.,  $C$ ) and standard deviation are much smaller than  $N - 1$  in the parameter range of interest (i.e.,  $C = O(1)$  or smaller), rendering the network approximately regular. Therefore, the present results are considered to be robust with respect to the updating rule.

The two-clique graph can be regarded as a simple multilayer network with two layers [15]. In this context, the Laplacian spectrum of multilayer networks in which each layer is a general network is a useful tool [29, 30]. Analysing the current model and its extensions under the framework of multilayer networks warrants future work.

### **Appendix: Mean consensus time when $C < 1$ via the coalescing random walk**

When  $C < 1$ , the state transition of the system of two coalescing random walkers on the two-clique graph is described by

$$\mathbf{p}(t + 1) = A\mathbf{p}(t) \tag{16}$$

and

$$r(t + 1) = \mathbf{v}\mathbf{p}(t), \tag{17}$$

where

$$\mathbf{p}(t) = (p_1(t) \ p_2(t) \ \cdots \ p_6(t))^{\top}, \tag{18}$$

$\top$  denotes the transposition,

$$A = \frac{1}{\Delta} \times \begin{pmatrix} \Delta - 2NC - 2 & N(1 - C) - 1 & 0 & 0 & 0 & 0 \\ 2NC & \Delta - N - 1 & 1 & 0 & 2N(1 - C) & 0 \\ 0 & 1 & \Delta - N - 1 & 2NC & 0 & 2N(1 - C) \\ 0 & 0 & N(1 - C) & \Delta - 2NC & 0 & 0 \\ 0 & NC - 1 & 0 & 0 & \Delta - 2N(1 - C) - 4 & 2\left(1 - \frac{1}{NC}\right) \\ 0 & 0 & NC & 0 & 2 & \Delta - 2N(1 - C) - 2 \end{pmatrix}, \quad (19)$$

$$\mathbf{v} = \frac{1}{\Delta} \begin{pmatrix} 2 & 2 & 0 & 0 & 2 & \frac{2}{NC} \end{pmatrix}, \quad (20)$$

and

$$\Delta = 2N(N + C - 1) \quad (21)$$

is twice the number of links.

By adapting Eq. (13) to the present system with six states, I obtain

$$r(t) = \mathbf{x}\mathbf{p}(0), \quad (22)$$

where  $\mathbf{x} = (x_1 \cdots x_6)$  is the solution of

$$\mathbf{x}(I - A) = (1 \cdots 1). \quad (23)$$

In fact, I obtain

$$\mathbf{x} = c_0 \begin{pmatrix} 2N(N^3C + 3N^2C + 3NC + 2C + 1)C \\ 2N^4C^2 + N^3(6C^2 + C) + N^2(5C^2 + 2C) + N(2C^2 + 3C) + 2C + 1 \\ N^4(2C^2 + C) + N^3(7C^2 + 5C) + N^2(5C^2 + 5C) + N(2C^2 + 5C + 1) + 2C + 1 \\ N^4(2C^2 + C) + N^3(7C^2 + 6C) + N^2(6C^2 + 9C) + N(4C^2 + 10C + 1) + 4C + 2 \\ 2N^2(N + 1)(NC + 2C + 1)C \\ N[N^3(2C^2 + C) + N^2(7C^2 + 4C) + N(4C^2 + C) - 2C - 1] \end{pmatrix}, \quad (24)$$

where

$$c_0 = \frac{N + C - 1}{[N^3C + N^2(C^2 + 4C) + N(2C^2 + 5C) + 2C + 1]C}. \quad (25)$$

Given  $C > 1/N$  by definition, Eq. (25) implies  $c_0 = O(1/N^2 C^2)$  as  $N \rightarrow \infty$ . Therefore, Eq. (24) implies that  $x_1, x_2, x_5 = O(N^2)$  and  $x_3, x_4, x_6 = O(N^2/C)$ . Therefore,  $r(t) = O(N^2/C)$  in general. I implicitly normalised the time for the sake of the present analysis such that each node is updated once per time  $2N$  on average. In terms of the rescaled time such that each node is updated once per unit time on average, I obtain  $r(t) = O(N/C)$ .

### Acknowledgments

I thank Sid Redner for valuable discussion throughout the current work. I also thank Yuni Iwamasa and Taro Takaguchi for careful reading of the manuscript. N.M. acknowledges the support provided through CREST JST.

FIG. 1: Distribution of  $T$  on the basis of  $10^4$  runs. I set  $N = 10^4$  and  $M = 1$ . The vertical axis represents the fraction of runs that fall in the time window specified on the horizontal axis.

FIG. 2: Schematic of the four classes of nodes when  $C < 1$ .

FIG. 3: Schematic of the six states of the coalescing random walk when  $C < 1$ . It should be noted that clique 1 may correspond to either the left or right clique in the figure.

FIG. 4: Relationship between the normalised mean consensus time,  $\langle T \rangle / N$ , and the number of interclique links per node,  $M/N$ . The solid line represents the relationship  $\langle T \rangle / N \propto (M/N)^{-1}$  as guides to the eye.
